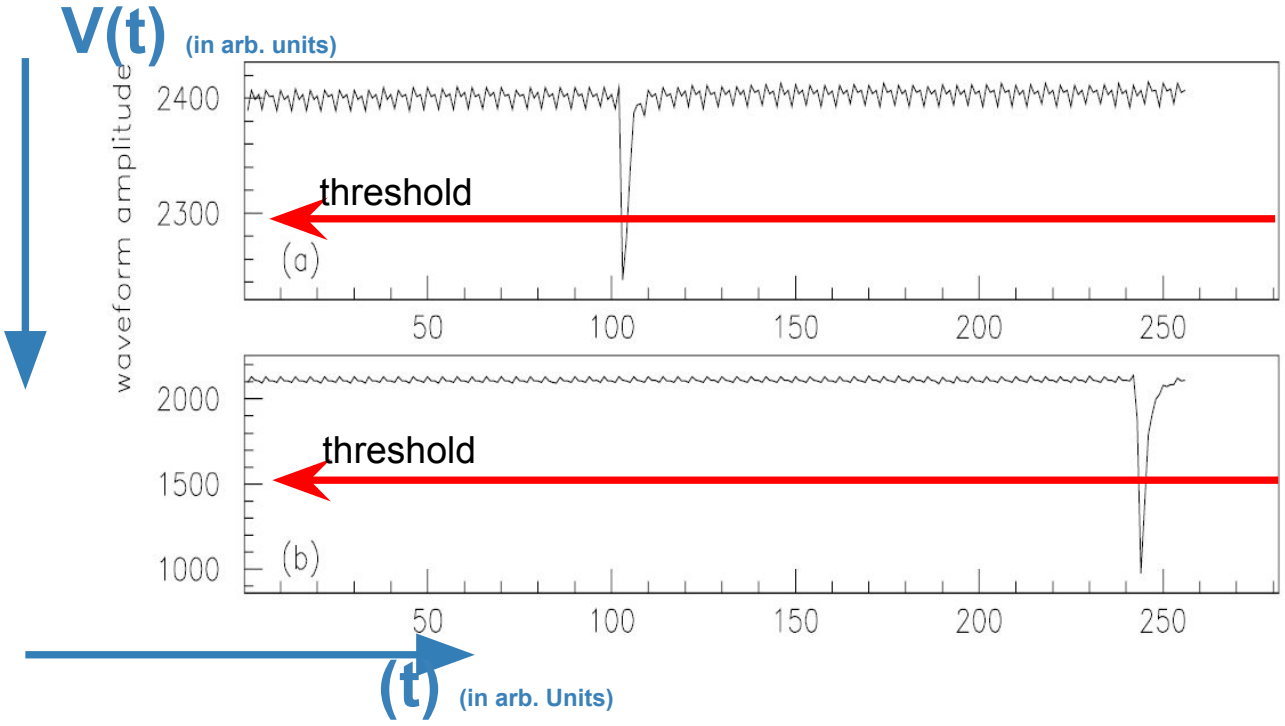
September 14, 2015, 09:50:45 UTC

Time series *x(t), x(n)*



Time domain analysis: little information in the frequency content; count particles, integrate charge etc.

Time-frequency information

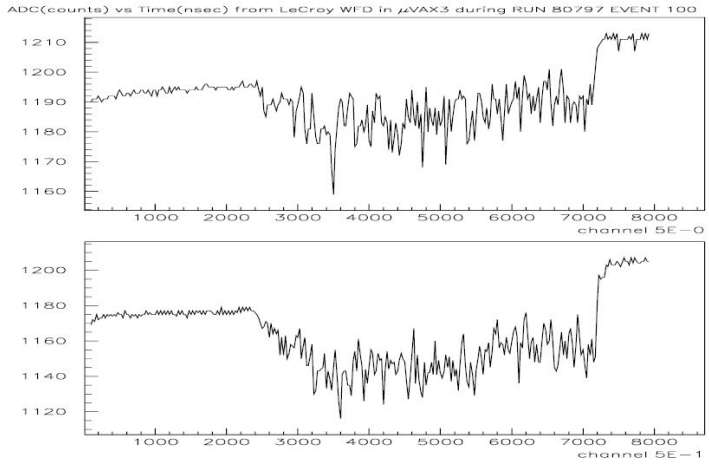


Figure 5.1: Typical LED-induced event as recorded by the WFDs during RUN 80797. The pulse width driving the LEDs was approximately $5\mu s$. The recorded waveforms show the typical LED risetime. A few thousand photoelectrons are included in each of the waveforms.

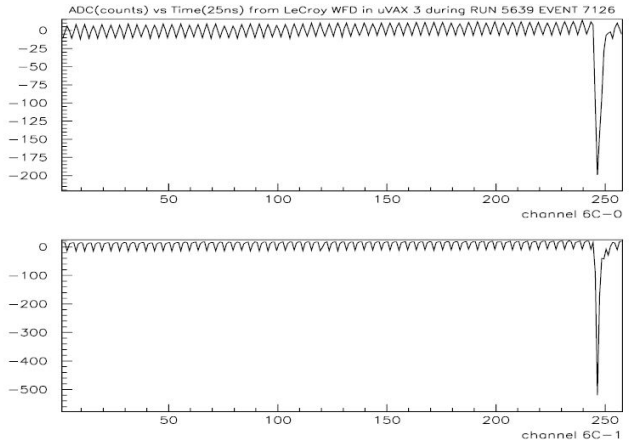

Figure D.3: Both of the above waveforms have been identified by means of the Haar transform as sharp ones. Although their apparent pulse height and pulse integral (number of photoelectrons) should have been enough to trigger the ERP in both ends of the tank, the ERP failed to fire.

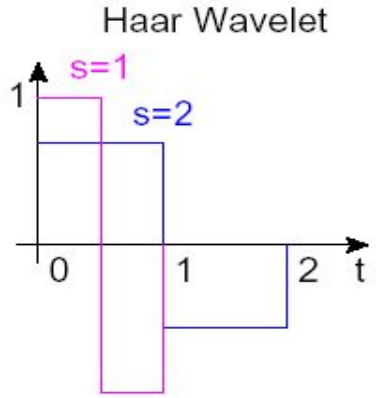
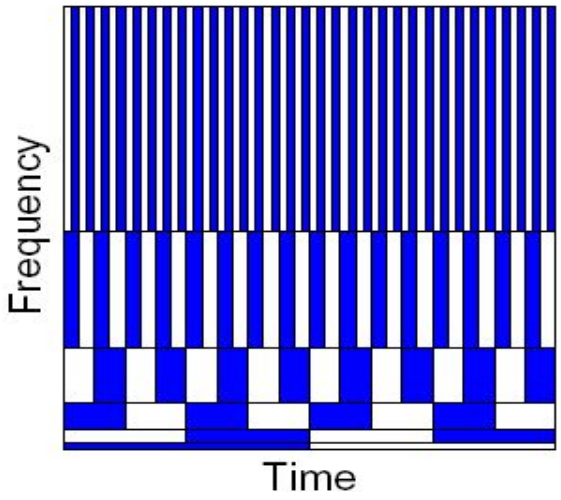
Time-frequency localization

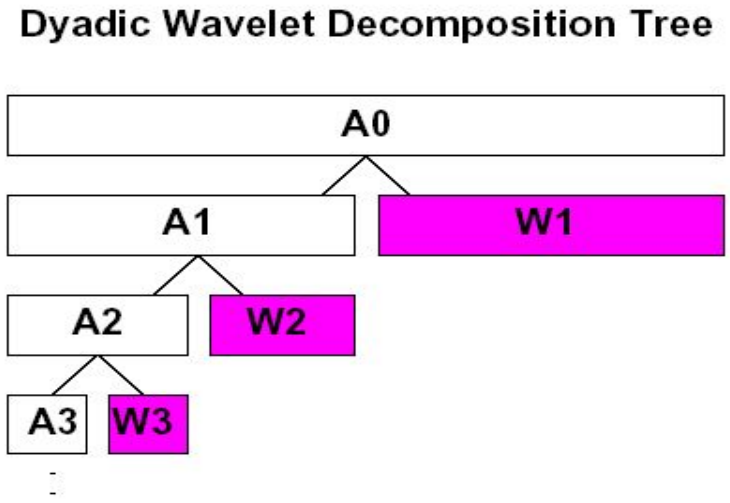
Multiresolution techniques

Project $x[n]$ onto time-shifted and scaled wavelets.

$$X_W[m,s] = \sum_{n=0}^{N-1} x[n] \frac{1}{\sqrt{2^s}} \psi\left(\frac{(n-m)T}{2^s}\right)$$







Gravitational-wave detector data

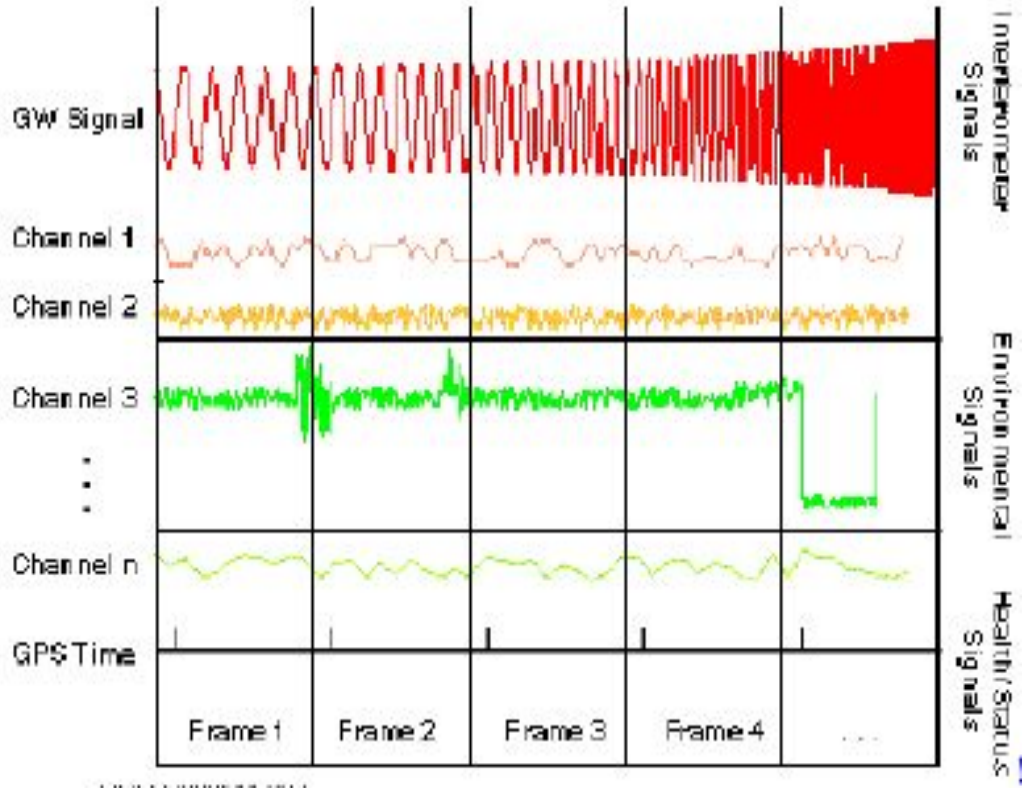
Continuous **time series** (1Hz, 128Hz … 16kHz)

Gravitational Wave channel:
~20GB/day (per instrument)

Physical Environment Monitors (seismometers, accelerometers, magnetometers, microphones etc)

Internal Engineering Monitors (sensing, housekeeping, status etc)

Together with various intermediate data products >2TB/day (per instrument)



The Q transform

Project whitened data onto multiresolution basis of minimum uncertainty waveforms

$$X(\tau, \phi, Q) = \int_{-\infty}^{+\infty} x(t)\, w(t-\tau, \phi, Q)\, e^{-i2\pi\phi t}\, dt$$

Abstract

We present two search algorithms that implement logarithmic tiling of the time–frequency plane in order to efficiently detect astrophysically unmodelled bursts of gravitational radiation. The first is a straightforward application of the dyadic wavelet transform. The second is a modification of the windowed Fourier transform which tiles the time–frequency plane for a specific Q. In addition, we also demonstrate adaptive whitening by linear prediction, which greatly simplifies our statistical analysis. This is a methodology paper that aims to describe the techniques for identifying significant events as well as the necessary pre-processing that is required in order to improve their performance. For this reason we use simulated LIGO noise in order to illustrate the methods and to present their preliminary performance.

Abstract. In this paper we describe the performance of the WaveBurst algorithm which was designed for detection of gravitational wave bursts in interferometric data. The performance of the algorithm was evaluated on the test data set collected during the second LIGO Scientific run. We have measured the false alarm rate of the algorithm as a function of the threshold and estimated its detection efficiency for simulated burst waveforms.

How can one claim a first detection in rare event searches?

Can one claim a first detection based on a single event?

Can one run an experiment with zero background?

First Results from a Superconductive Detector for Moving Magnetic Monopoles

Blas Cabrera
Physics Department, Stanford University, Stanford, California 94305
(Received 5 April 1982)

A velocity- and mass-independent search for moving magnetic monopoles is being performed by continuously monitoring the current in a 20-cm^2-area superconducting loop. A single candidate event, consistent with one Dirac unit of magnetic charge, has been detected during five runs totaling 151 days.

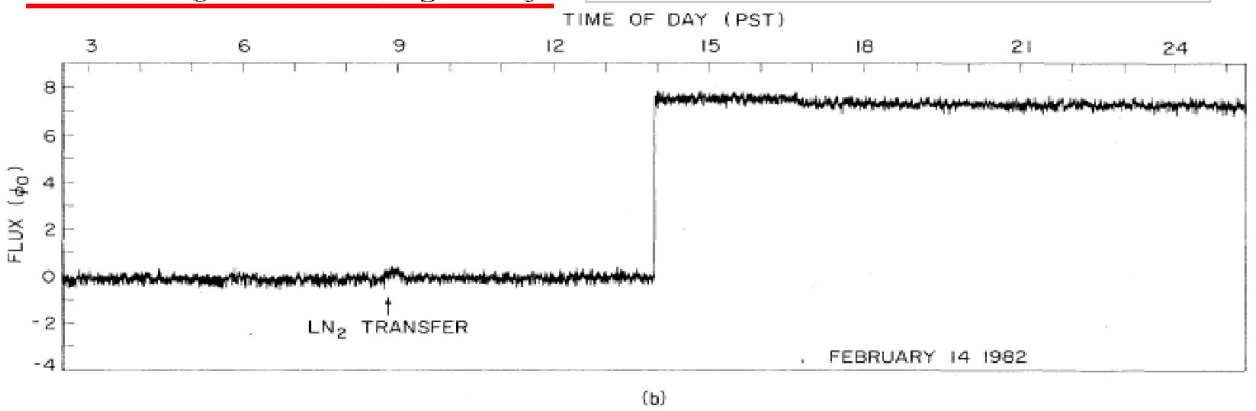

FIG. 2. Data records showing (a) typical stability and (b) the candidate monopole event.

Cabrera's "detection checklist" from PRL 48, 20 (1982)

Instrumental

- Calibration (detector response)
- Line voltage fluctuations
- RF interference
- External magnetic field
- Ferromagnetic contamination
- Critical current of the loop
- Mechanically induced offsets
- Seismic disturbance
- Energetic cosmic rays
- Spontaneous and large external mechanical impulse
- Spontaneous internal stress release mechanism

Physical interpretation

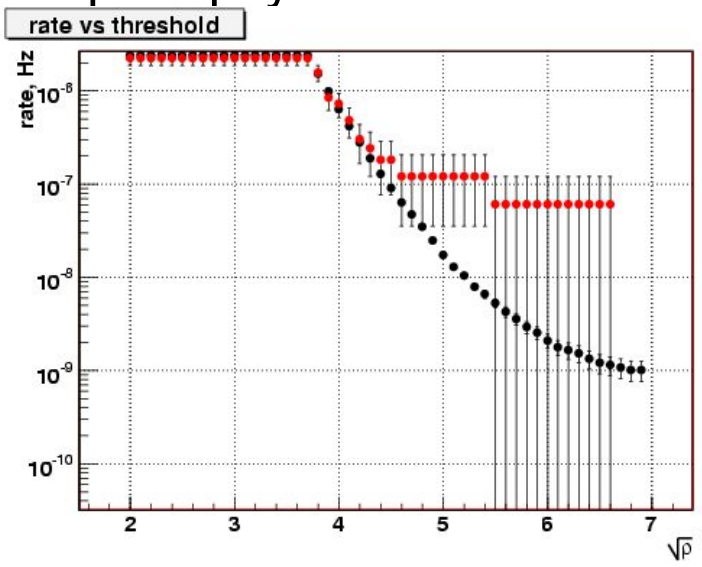
- Flux consistent with one Dirac unit of magnetic charge
- Local missing mass density: 0.05 M_solar/pc^3 made up of monopole of mass 10^{16}GeV at 300km/sec would result in 1.5 events per year through his detector

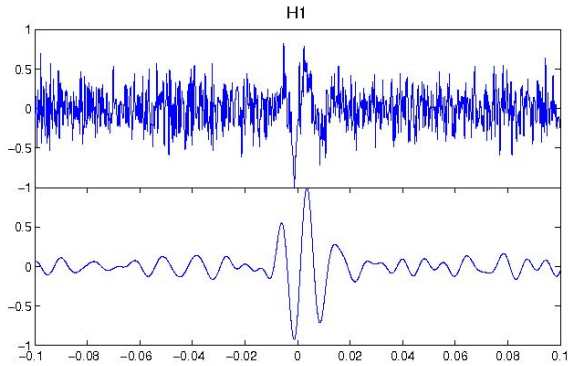
Blind injection challenges in GW detection

Two blind injections in the 2007 run and one blind injection in 2009

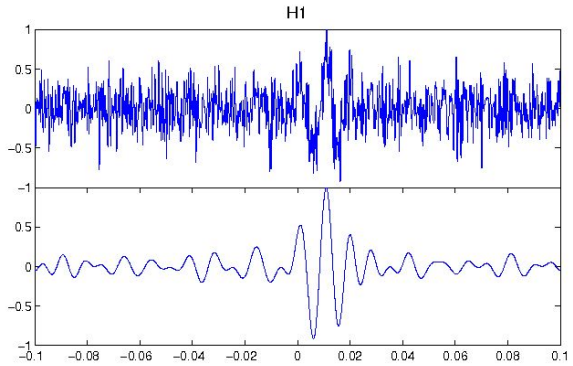
Extremely valuable in honing the ability to understand what it means to vet a gravitational-wave transient event to a level to call it astrophysical.

Many lessons learned in terms of the importance to look at the data promptly and in establishing detection follow-up criteria





Equinox event



Equal mass, no spin, 70+70 solar mass black hole merger

Detection checklist

https://wiki.ligo.org/Bursts/DetectionChecklist_S6_968654557 80%

Checklist

Please notice that some of the suggested checks may conflict with the notion of keeping ourselves blind from the possible blind injection. Do not undertake any such checks until after the blind injection challenge has been declared over.

Abstract

We investigate the behavior of small perturbations around the Kaluza-Klein monopole in the five dimensional space-time. We find that the even parity gravitational wave does not propagate in the five dimensional space-time with Kaluza-Klein monopole pro-
